

React Props

1. What are props
2. Using props
3. Default props
4. Validating props

1. What are props

- Props stand for "Properties"
- Props are used to supply the data to the component.
- Props are used as read only fashion by the component.
- To send props into a component, use the same syntax as HTML attributes.

2. Using props

- Props are sent to the component like attributes for HTML tag
- One component can be passed with multiple props while rendering.
- Accessing props from class component: `this.props.<propsname>`
- Accessing props from functional component:
`<name_of_argument>.<name_of_prop>`
- Sending props to components
`<Comp_name prop="value" prop1="value1" />`

- Sometimes renderer may not send the required props to the component while rendering which may lead to error.
- Fallback value
 - Use the logical operator `||` to set a fallback value so when prop is missing
- Using default props
 - `defaultProps` is a property in React component used to set default values for the props argument.
 - This property can be supplied with key-value pairs for props definition but will be used only when props are not passed while rendering the component.

- React components uses a special property called propTypes to setup data type validation
- propTypes property allows to specify the type of value we are expecting for a particular prop and it is possible to even set some restriction rule.
- When a prop is passed in with an invalid type or fails the prop type, a warning is passed into the JavaScript console
- To use Proptypes in React component, it needs to be installed using npm.
